Abstract

In this paper we provide a simple proof of the fact that for a system of two spin- $\frac{1}{2}$ particles, and for a choice of a set of observables, there is a unique state which shows Hardy-type nonlocality. Moreover, an explicit expression for the probability that an ensemble of particle pairs prepared in such a state exhibits a Hardy-type nonlocality contradiction is given in terms of two independent parameters related to the observables involved. Incidentally, a wrong statement expressed in Mermin's proof of the converse [N.D. Mermin, Am. J. Phys. **62**, 880 (1994)] is pointed out.

Key words: quantum mechanics, Hardy's nonlocality contradiction, two-particle entangled state, Schmidt decomposition.

1 Introduction

In his pioneering paper [1], John Bell established the first of a series of inequalities now collectively known as "Bell inequalities" which demonstrate the incompatibility between the predictions of quantum theory and the limitations imposed by a local and realistic world view. Bell showed that for an Einstein-Podolsky-Rosen-Bohm gedanken experiment [2,3], the quantum-mechanical predictions for an ensemble of pairs of spin- $\frac{1}{2}$ particles prepared

in the singlet state violate an inequality which must necessarily be satisfied by any physical theory based on the reality and locality postulates. More recently Hardy [4], by means of an ingenious thought experiment, managed to find a proof of nonlocality for two particles without using inequalities, with each of the particles living in an effective two-dimensional Hilbert state space. A more systematic version of this proof was given by Hardy himself [5], and then by Goldstein [6], Jordan [7,8], Aravind [9], and Cereceda [10], among other authors. In its simplest form, Hardy's nonlocality theorem involves the values of four dichotomic observables (two for each particle), and states that a direct contradiction between the quantum-mechanical and locally realistic predictions concerning such values can arise for some probabilistic fraction of an ensemble of particle pairs configured in an entangled state, provided that the entanglement is not maximal.

The converse of this result has also been proved [7,11-13]: for any choice of two different observables for each particle, a state can be found which admits a Hardy-type nonlocality contradiction. However, while Jordan's valuable treatment of the converse lacks some of the clearness required by a beginner student (in fact, Jordan's proof can be greatly simplified, as shown in Refs. [11-13]), Kar's remarkable proof deals only with abstract projection operators, without any reference to concrete physical measurable quantities. Regarding Mermin's instructive proof (see Sections I and II of Ref. [13]), I maintain that his conclusion that, "... we can do the trick with any two choices of nontrivial local one-particle observables to be measured in mode 1 on the right and on the left, and any state $|\Psi\rangle$ of the form (2) with three nonzero amplitudes α , β , and γ ", is not entirely correctly stated. Indeed, from Eq. (7) of Ref. [13], we can see that the magnitude of γ is fixed by the quantities $|\langle 2G | 1R \rangle_r|$, $|\langle 2G | 1G \rangle_r|$, $|\langle 2G | 1R \rangle_l|$, and $|\langle 2G | 1G \rangle_l|$. Likewise, from Eqs. (3), (4), and (7) of Ref. [13], we can readily express the magnitude of α and β in terms of the four quantities above. On the other hand, from Eq. (3) [(4)] of Ref. [13], it follows that the phase of β [α] is in turn determined by the phases of $\langle 2G | 1R \rangle_r$ and $\langle 2G | 1G \rangle_r$ [$\langle 2G | 1R \rangle_l$ and $\langle 2G | 1G \rangle_l$] (without loss of generality, we may choose the amplitude γ to be real). So, strictly speaking, the trick will only work for that state $|\Psi\rangle$ whose (nonzero) coeffi-

cients α , β , and γ *do* satisfy simultaneously the above set of Eqs. (3), (4), and (7). What Mermin actually proves is a version of the converse of Hardy’s theorem, in which both nontrivial one-particle observables for mode 1 on the right and on the left are *quite* arbitrary (in Mermin’s words, “You can pick any two one-particle observables you like for the detectors to measure when their switches are set to 1”), both one-particle observables for mode 2 on the right and on the left are *almost* arbitrary (in Mermin’s words, “The choices of the two observables measured by the detectors in modes 2 are almost as flexible”), and where, as a result, the state $|\Psi\rangle$ turns out to be fixed (up to an arbitrary overall phase factor) by the above choice of four observables through the Eqs. (2), (3), (4), and (7) of Ref. [13]. As Mermin then shows, the probability of getting the “impossible” $22GG$ events is maximum for those choices of observables for which $|\langle 2G | 1G \rangle_l|^2 = |\langle 2G | 1G \rangle_r|^2 = \tau^{-1}$, and $|\langle 2G | 1R \rangle_l|^2 = |\langle 2G | 1R \rangle_r|^2 = 1 - \tau^{-1}$, with τ being the golden mean, $\frac{1}{2}(1 + \sqrt{5})$.

Following Mermin’s treatment, in this paper we present a direct, easy-to-grasp proof of the converse of Hardy’s theorem for two spin- $\frac{1}{2}$ particles (which we call a and b) that achieves a certain generality while retaining the mathematical simplicity. This proof makes clear the fact that, for two spin- $\frac{1}{2}$ particles and for a given choice of observables, there is a unique state which satisfies Hardy’s nonlocality. Moreover, a graphical representation of the probability for a Hardy-type contradiction (see Eq. (9) and Fig. 1 below) is given in terms of two independent parameters related to the observables involved. For this purpose, we consider the spin components of each particle along directions lying within the x - z plane, so that we shall deal with the observables $S(\theta_a)$ and $S(\theta'_a)$ for particle a , and $S(\theta_b)$ and $S(\theta'_b)$ for particle b , with $S(\theta_a)$, $S(\theta'_a)$, $S(\theta_b)$, and $S(\theta'_b)$ being spin components along directions making an angle θ_a , θ'_a , θ_b , and θ'_b , respectively, with the z axis in the x - z plane (of course it is understood that the z axis is defined with reference to in general different coordinate systems for each of the particles). Further, as usual, it is assumed that each of the spin components yields the outcome $+1$ or -1 (in appropriate units) if measured.

2 The converse of Hardy's theorem

A two-particle state $|\eta\rangle$ exhibits a Hardy-type nonlocality contradiction if there exist two observables for each particle—say, $S(\theta_a)$ and $S(\theta'_a)$ for particle a , and $S(\theta_b)$ and $S(\theta'_b)$ for particle b —such that the following four conditions are simultaneously fulfilled for the state $|\eta\rangle$ ¹

$$P_\eta(S(\theta_a) = +1, S(\theta_b) = +1) = 0, \quad (1a)$$

$$P_\eta(S(\theta_a) = -1, S(\theta'_b) = -1) = 0, \quad (1b)$$

$$P_\eta(S(\theta'_a) = -1, S(\theta_b) = -1) = 0, \quad (1c)$$

$$P_\eta(S(\theta'_a) = -1, S(\theta'_b) = -1) > 0, \quad (1d)$$

where, for example, $P_\eta(S(\theta_a) = +1, S(\theta_b) = +1)$ denotes the probability that a joint measurement of the observables $S(\theta_a)$ and $S(\theta_b)$ on particles a and b , respectively, gives the result $+1$ for both observables when the particles are described by the state vector $|\eta\rangle$. As we have said, every entangled state except those maximally entangled (such as the singlet state considered by Bell) shows Hardy-type contradiction, that is, there are observables $S(\theta_a)$, $S(\theta'_a)$, $S(\theta_b)$ and $S(\theta'_b)$ (in fact, there are an infinite number of them [6,7,10]) for which the conditions (1a)-(1d) are fulfilled for the entangled state. That conditions (1a)-(1d) lead to a contradiction with the assumption of local realism can be seen as follows [5]. Consider a particular run of the experiment for which the observables $S(\theta'_a)$ and $S(\theta'_b)$ are measured on a pair of space-like separated particles a and b in the state $|\eta\rangle$, and the results $S(\theta'_a) = -1$ and $S(\theta'_b) = -1$ are obtained. From Eq. (1d), there is a nonzero probability for these joint measurement results to occur. By invoking local realism, and taking into account the constraint in Eq. (1c), one could assert that a result $S(\theta_b) = +1$ would have been obtained if, instead of $S(\theta'_b)$, the observable $S(\theta_b)$ had been measured on particle b . Similarly, from Eq. (1b), and applying local realism, one might conclude that a result $S(\theta_a) = +1$ would have been obtained for a measurement of $S(\theta_a)$ on particle a . In this way, the quantum predictions (1d), (1c), and (1b), together with the assumption of local realism, allows one to deduce that there must be a nonzero probability to obtain the results $S(\theta_a) = +1$ and $S(\theta_b) = +1$ in a joint measurement of

the observables $S(\theta_a)$ and $S(\theta_b)$. However, from Eq. (1a), we cannot have simultaneously the results $S(\theta_a) = +1$ and $S(\theta_b) = +1$ for any pairs of particles described by $|\eta\rangle$. Hence a contradiction between quantum mechanics and local realism arises without using inequalities.

It is convenient to introduce the relative angles $\theta_1 = \theta'_a - \theta_a$ and $\theta_2 = \theta'_b - \theta_b$. We are now ready to prove the converse of Hardy's theorem. Specifically, we show that for any choice of θ_a , θ'_a , θ_b , and θ'_b (or, equivalently, for any choice of θ_a , θ_b , θ_1 , and θ_2), there exists a two-particle state $|\eta\rangle$ satisfying the above conditions (1a)-(1d), provided that both θ_1 and θ_2 are not an integral multiple of π . To do this, we first write the quantum state in terms of eigenvectors for the $S(\theta_a)$ component of particle a and $S(\theta_b)$ component of particle b

$$|\eta\rangle = c_{++} |S(\theta_a) = +1\rangle |S(\theta_b) = +1\rangle + c_{+-} |S(\theta_a) = +1\rangle |S(\theta_b) = -1\rangle \\ + c_{-+} |S(\theta_a) = -1\rangle |S(\theta_b) = +1\rangle + c_{--} |S(\theta_a) = -1\rangle |S(\theta_b) = -1\rangle, \quad (2)$$

where, for example, $|S(\theta_a) = +1\rangle$ represents a state of spin-up for particle a along a direction inclined at an angle θ_a to the z axis in the x - z plane. The coefficients c_{++} , c_{+-} , c_{-+} , and c_{--} (which, for simplicity, are assumed to be real—the extension to complex coefficients offering no difficulty) obey the normalization condition

$$c_{++}^2 + c_{+-}^2 + c_{-+}^2 + c_{--}^2 = 1. \quad (3)$$

Of course the expansion (2) is always possible since the set of product vectors $\{|S(\theta_a) = i\rangle |S(\theta_b) = j\rangle\}$, with $i, j = +1$ or -1 , span the total four-dimensional Hilbert space associated with the spin of particles a and b . Clearly, condition (1a) does hold for the state vector $|\eta\rangle$ if, and only if, $c_{++} = 0$. On the other hand, by expressing the eigenvectors $|S(\theta_a) = +1\rangle$ and $|S(\theta_a) = -1\rangle$ in terms of $|S(\theta'_a) = +1\rangle$ and $|S(\theta'_a) = -1\rangle$,

$$|S(\theta_a) = +1\rangle = \cos \frac{\theta_1}{2} |S(\theta'_a) = +1\rangle - \sin \frac{\theta_1}{2} |S(\theta'_a) = -1\rangle, \quad (4a)$$

$$|S(\theta_a) = -1\rangle = \sin \frac{\theta_1}{2} |S(\theta'_a) = +1\rangle + \cos \frac{\theta_1}{2} |S(\theta'_a) = -1\rangle, \quad (4b)$$

and the eigenvectors $|S(\theta_b) = +1\rangle$ and $|S(\theta_b) = -1\rangle$ in terms of $|S(\theta'_b) = +1\rangle$ and $|S(\theta'_b) = -1\rangle$,

$$|S(\theta_b) = +1\rangle = \cos \frac{\theta_2}{2} |S(\theta'_b) = +1\rangle - \sin \frac{\theta_2}{2} |S(\theta'_b) = -1\rangle, \quad (5a)$$

$$|S(\theta_b) = -1\rangle = \sin \frac{\theta_2}{2} |S(\theta'_b) = +1\rangle + \cos \frac{\theta_2}{2} |S(\theta'_b) = -1\rangle, \quad (5b)$$

it is immediate to see that the fulfillment of conditions (1b) and (1c) is equivalent to requiring, respectively, that

$$c_{--} \cos \left(\frac{\theta_2}{2} \right) - c_{-+} \sin \left(\frac{\theta_2}{2} \right) = 0, \quad (6)$$

and

$$c_{--} \cos \left(\frac{\theta_1}{2} \right) - c_{+-} \sin \left(\frac{\theta_1}{2} \right) = 0. \quad (7)$$

(Note that the pair of Eqs. (6) and (7) is the equivalent of Mermin's pair of Eqs. (3) and (4) in Ref. [13].) Relations (6) and (7), together with the normalization condition (3), allow us to solve for the coefficients c_{-+} , c_{+-} , and c_{--} , expressed as a function of the parameters θ_1 and θ_2 . A straightforward calculation gives

$$c_{-+} = \pm \frac{\tan \left(\frac{\theta_1}{2} \right)}{\left[\tan^2 \left(\frac{\theta_1}{2} \right) + \tan^2 \left(\frac{\theta_2}{2} \right) + \tan^2 \left(\frac{\theta_1}{2} \right) \tan^2 \left(\frac{\theta_2}{2} \right) \right]^{\frac{1}{2}}}, \quad (8a)$$

$$c_{+-} = \pm \frac{\tan \left(\frac{\theta_2}{2} \right)}{\left[\tan^2 \left(\frac{\theta_1}{2} \right) + \tan^2 \left(\frac{\theta_2}{2} \right) + \tan^2 \left(\frac{\theta_1}{2} \right) \tan^2 \left(\frac{\theta_2}{2} \right) \right]^{\frac{1}{2}}}, \quad (8b)$$

$$c_{--} = \pm \frac{\tan \left(\frac{\theta_1}{2} \right) \tan \left(\frac{\theta_2}{2} \right)}{\left[\tan^2 \left(\frac{\theta_1}{2} \right) + \tan^2 \left(\frac{\theta_2}{2} \right) + \tan^2 \left(\frac{\theta_1}{2} \right) \tan^2 \left(\frac{\theta_2}{2} \right) \right]^{\frac{1}{2}}}. \quad (8c)$$

The state vector (2) with coefficients c_{-+} , c_{+-} , and c_{--} given by Eqs. (8a)-(8c), and the coefficient c_{++} set to zero, satisfies the Hardy equations (1a)-(1c). It remains to check out that, for such a state, the probability $P_\eta(S(\theta'_a) = -1, S(\theta'_b) = -1)$ is nonzero almost everywhere. This probability is a measure of the statistical fraction of particle pairs prepared in the state $|\eta\rangle$, for which a joint measurement of $S(\theta'_a)$ and $S(\theta'_b)$ gives results

which, when combined with the quantum predictions (1a)-(1c), cannot be explained by any locally realistic theory. On using the coefficients (8a)-(8c) in expansion (2), and replacing the eigenvectors $|S(\theta_a) = +1\rangle$, $|S(\theta_a) = -1\rangle$, $|S(\theta_b) = +1\rangle$, and $|S(\theta_b) = -1\rangle$ with the corresponding expression (4a), (4b), (5a), and (5b), one finds that the above probability is given by

$$P_\eta(S(\theta_a + \theta_1) = -1, S(\theta_b + \theta_2) = -1) = \frac{\sin^2\left(\frac{\theta_1}{2}\right) \sin^2\left(\frac{\theta_2}{2}\right)}{\tan^2\left(\frac{\theta_1}{2}\right) + \tan^2\left(\frac{\theta_2}{2}\right) + \tan^2\left(\frac{\theta_1}{2}\right) \tan^2\left(\frac{\theta_2}{2}\right)}. \quad (9)$$

This function is represented in Fig. 1 for the ranges of variation $0^\circ \leq \theta_1 \leq 360^\circ$ and $0^\circ \leq \theta_2 \leq 360^\circ$. The probability function (9) is found to vanish wherever $\theta_1 = n_1\pi$, or $\theta_2 = n_2\pi$, with $n_1, n_2 = 0, \pm 1, \pm 2, \dots$. Except for these values of θ_1 or θ_2 the above probability is positive. The vanishing of (9) corresponds to the case in which the observables $S(\theta_a)$ and $S(\theta'_a)$, or $S(\theta_b)$ and $S(\theta'_b)$, happen to commute. So we have proved that for any two pairs of noncommuting observables, $S(\theta_a)$ and $S(\theta'_a)$ for particle a , and $S(\theta_b)$ and $S(\theta'_b)$ for particle b , a two-particle state exists that fulfills the conditions (1a)-(1d). As we have said, this state is given by Eq. (2) with $c_{++} = 0$, and c_{-+} , c_{+-} , and c_{--} given by Eqs. (8a)-(8c). It is important to notice that the state vector (2) satisfying the set of equations (1a)-(1d) for given θ_a , θ'_a , θ_b , and θ'_b is unique up to an arbitrary overall phase factor. This follows from the fact that, (i) the eigenvectors $|S(\theta_a) = +1\rangle$ and $|S(\theta_a) = -1\rangle$ [$|S(\theta_b) = +1\rangle$ and $|S(\theta_b) = -1\rangle$] appearing in expansion (2) are uniquely determined by the angle θ_a [θ_b]; and (ii) the expansion coefficients c_{-+} , c_{+-} , and c_{--} satisfying the relations (3), (6), and (7) (with the coefficient c_{++} set to zero in Eq. (3)) are unique (up to a common sign factor) for fixed values of θ_1 and θ_2 . This uniqueness implies that no mixture state for two spin- $\frac{1}{2}$ particles admits Hardy's nonlocality for fixed choice of observables [11,12].

Now, according to Mermin's theory [13], and making the identifications

$$\begin{aligned} |S(\theta'_a) = -1\rangle &\equiv |2G\rangle_l; & |S(\theta'_b) = -1\rangle &\equiv |2G\rangle_r, \\ |S(\theta'_a) = +1\rangle &\equiv |2R\rangle_l; & |S(\theta'_b) = +1\rangle &\equiv |2R\rangle_r, \\ |S(\theta_a) = -1\rangle &\equiv |1G\rangle_l; & |S(\theta_b) = -1\rangle &\equiv |1G\rangle_r, \\ |S(\theta_a) = +1\rangle &\equiv |1R\rangle_l; & |S(\theta_b) = +1\rangle &\equiv |1R\rangle_r, \end{aligned} \quad (10)$$

it follows that the probability (9) is maximum for those choices of $\theta_a, \theta'_a, \theta_b,$ and θ'_b for which

$$\left| \left\langle S(\theta'_a) = -1 \mid S(\theta_a) = -1 \right\rangle \right|^2 = \left| \left\langle S(\theta'_b) = -1 \mid S(\theta_b) = -1 \right\rangle \right|^2 = \tau^{-1}, \quad (11a)$$

and

$$\left| \left\langle S(\theta'_a) = -1 \mid S(\theta_a) = +1 \right\rangle \right|^2 = \left| \left\langle S(\theta'_b) = -1 \mid S(\theta_b) = +1 \right\rangle \right|^2 = 1 - \tau^{-1}. \quad (11b)$$

From Eqs. (4b) and (5b), condition (11a) implies that $\cos^2(\frac{\theta_1}{2}) = \cos^2(\frac{\theta_2}{2}) = \tau^{-1}$. Analogously, from Eqs. (4a) and (5a), condition (11b) implies that $\sin^2(\frac{\theta_1}{2}) = \sin^2(\frac{\theta_2}{2}) = 1 - \tau^{-1}$. For the ranges of variation $0^\circ \leq \theta_1 \leq 360^\circ$ and $0^\circ \leq \theta_2 \leq 360^\circ$, these conditions are fulfilled for the following pairs of values (see Fig. 1): $(\theta_1, \theta_2) = (\theta_0, \theta_0), (\theta_0, 2\pi - \theta_0), (2\pi - \theta_0, \theta_0),$ and $(2\pi - \theta_0, 2\pi - \theta_0)$, with $\theta_0 \simeq 76.3454^\circ$. For any one of these pairs, the probability function (9) attains the maximum value $P_\eta^{\max} = 1/\tau^5$, while the squared coefficients $c_{-+}^2, c_{+-}^2,$ and c_{--}^2 yielding this maximum probability are

$$\begin{aligned} c_{-+}^2 &= c_{+-}^2 = 1/\tau^2, \\ c_{--}^2 &= 1/\tau^3. \end{aligned} \quad (12)$$

Naturally, according to Eq. (3), we have $2/\tau^2 + 1/\tau^3 = 1$.

On the other hand, as mentioned above, the probability (9) is zero for either $\theta_1 = n_1\pi$ or $\theta_2 = n_2\pi$, so that the nonlocality argument will fail as soon as any one of the four quantities $|\langle S(\theta'_a) = -1 \mid S(\theta_a) = i \rangle|,$ $|\langle S(\theta'_b) = -1 \mid S(\theta_b) = j \rangle|$, with $i, j = +1$ or -1 , happens to vanish. This is just the reason why the choice of all four observables $S(\theta_a), S(\theta'_a), S(\theta_b),$ and $S(\theta'_b)$, cannot be totally arbitrary. As Mermin points out [13], in order for the argument to run, it is necessary that the eigenvector $|S(\theta'_a) = -1\rangle$ [$|S(\theta'_b) = -1\rangle$] has nonzero components along both $|S(\theta_a) = +1\rangle$ and $|S(\theta_a) = -1\rangle$ [$|S(\theta_b) = +1\rangle$ and $|S(\theta_b) = -1\rangle$]. Clearly the fulfillment of this condition guarantees that the eigenvector $|S(\theta'_a) = +1\rangle$ [$|S(\theta'_b) = +1\rangle$] has equally nonzero components along both $|S(\theta_a) = +1\rangle$ and $|S(\theta_a) = -1\rangle$

[$|S(\theta_b) = +1\rangle$ and $|S(\theta_b) = -1\rangle$]. By the way we note that the above conditions (11a) and (11b) defining the maxima of the probability function (9) can be written equivalently as

$$\left| \left\langle S(\theta'_a) = +1 \mid S(\theta_a) = -1 \right\rangle \right|^2 = \left| \left\langle S(\theta'_b) = +1 \mid S(\theta_b) = -1 \right\rangle \right|^2 = 1 - \tau^{-1}, \quad (13a)$$

and

$$\left| \left\langle S(\theta'_a) = +1 \mid S(\theta_a) = +1 \right\rangle \right|^2 = \left| \left\langle S(\theta'_b) = +1 \mid S(\theta_b) = +1 \right\rangle \right|^2 = \tau^{-1}, \quad (13b)$$

respectively. Likewise, the vanishing of any one of the four quantities $|\langle S(\theta'_a) = +1 \mid S(\theta_a) = i \rangle|$, $|\langle S(\theta'_b) = +1 \mid S(\theta_b) = j \rangle|$, means that the probability (9) is zero.² It will further be noted that for the particular case in which $\theta_1 = \theta_2 \equiv \theta$, expression (9) reduces to

$$P_\eta(S(\theta_a + \theta) = -1, S(\theta_b + \theta) = -1) = \frac{\sin^2 \theta}{4 + 4 \sec^2 \left(\frac{\theta}{2} \right)}, \quad (14)$$

while the coefficients c_{-+} , c_{+-} , and c_{--} are found to be

$$c_{-+} = c_{+-} = \pm \left[2 + \tan^2 \left(\frac{\theta}{2} \right) \right]^{-\frac{1}{2}}, \quad (15)$$

$$c_{--} = \pm \left[1 + 2 \cot^2 \left(\frac{\theta}{2} \right) \right]^{-\frac{1}{2}}. \quad (16)$$

The probability function (14) is plotted in Fig. 2.

3 Concluding remarks

We conclude by noting that the lack of one of the terms in expansion (2) prevents the state vector $|\eta\rangle$ from being maximally entangled. To see this, recall that, according to the Schmidt decomposition theorem [9,14,15], any pure spin state for two spin- $\frac{1}{2}$ particles can be expressed as a sum of two biorthogonal terms. In particular, the state vector (2) with $c_{++} = 0$, and c_{-+} , c_{+-} , and c_{--} given by Eqs. (8a)-(8c), can be put in the form

$$|\eta\rangle = c_+ |S(\phi_a) = +1\rangle |S(\phi_b) = +1\rangle + c_- |S(\phi_a) = -1\rangle |S(\phi_b) = -1\rangle, \quad (17)$$

for some appropriate c_+ and c_- depending on θ_1 and θ_2 , and some appropriate ϕ_a (ϕ_b) depending on θ_a , θ_1 , and θ_2 (θ_b , θ_1 , and θ_2), with the real coefficients c_+ and c_- fulfilling $c_+^2 + c_-^2 = 1$, and where the polar angles ϕ_a and ϕ_b define the orientation of two axes in the x - z plane. Without any loss of generality, we may assume that $c_+^2 \geq c_-^2$. The state in Eq. (17) is said to be maximally entangled if c_+ and c_- are equal in absolute value, that is, if $c_+^2 = c_-^2 = \frac{1}{2}$. We want to show that the state vector (2) with $c_{++} = 0$ does not admit a decomposition like that of Eq. (17) for which $c_+^2 = c_-^2$. This follows in a rather straightforward way from the easily confirmed fact that, whenever $|c_+| = |c_-|$, the state vector (17) implies that

$$P_\eta(S(\theta_a) = +1, S(\theta_b) = +1) = P_\eta(S(\theta_a) = -1, S(\theta_b) = -1). \quad (18)$$

However, for the case in which c_{++} is equal to zero, we have from Eq. (2) that $P_\eta(S(\theta_a) = +1, S(\theta_b) = +1) = 0$. On the other hand, the probability $P_\eta(S(\theta_a) = -1, S(\theta_b) = -1) = c_{--}^2$ is in general different from zero, as can be seen from Eq. (8c) or (16). This contradiction establishes that the state vector satisfying the conditions (1a)-(1d) for given θ_a , θ'_a , θ_b , and θ'_b , cannot be maximally entangled. This is consistent of course with the fact that no maximally entangled state for two spin- $\frac{1}{2}$ particles can give a Hardy-type nonlocality contradiction [5-10].

For the sake of completeness, let us now briefly sketch how one can find the decomposition (17) that obtains for a given state vector (2). (Recall that θ_a , θ_b , θ_1 , and θ_2 (with θ_1 , $\theta_2 \neq 0$ or π) are arbitrary but fixed parameters, and that the coefficient c_{++} is set to zero throughout.) The density matrix associated with the pure state (2) is $\rho = |\eta\rangle \langle \eta|$, and the corresponding reduced density matrices describing the spin of particles a and b are, respectively, $\rho_a = \text{Tr}_b \rho$ and $\rho_b = \text{Tr}_a \rho$, where Tr_a (Tr_b) denotes the trace operation over the spin states of particle a (b). In our case, ρ is a 4×4 symmetric matrix, whereas both ρ_a and ρ_b are 2×2 symmetric matrices. All these density matrices are most easily written down when the two orthonormal Hilbert space

vectors $\begin{pmatrix} 1 \\ 0 \end{pmatrix}_a$ and $\begin{pmatrix} 0 \\ 1 \end{pmatrix}_a$ for particle a are chosen such that

$$|S(\theta_a) = +1\rangle \equiv \begin{pmatrix} 1 \\ 0 \end{pmatrix}_a, \quad |S(\theta_a) = -1\rangle \equiv \begin{pmatrix} 0 \\ 1 \end{pmatrix}_a, \quad (19a)$$

and, similarly, the basis vectors $\begin{pmatrix} 1 \\ 0 \end{pmatrix}_b$ and $\begin{pmatrix} 0 \\ 1 \end{pmatrix}_b$ for particle b are chosen such that

$$|S(\theta_b) = +1\rangle \equiv \begin{pmatrix} 1 \\ 0 \end{pmatrix}_b, \quad |S(\theta_b) = -1\rangle \equiv \begin{pmatrix} 0 \\ 1 \end{pmatrix}_b. \quad (19b)$$

In this representation the reduced density matrices ρ_a and ρ_b read as

$$\rho_a = \begin{pmatrix} c_{+-}^2 & c_{+-}c_{--} \\ c_{+-}c_{--} & c_{-+}^2 + c_{--}^2 \end{pmatrix}, \quad (20a)$$

and

$$\rho_b = \begin{pmatrix} c_{-+}^2 & c_{-+}c_{--} \\ c_{-+}c_{--} & c_{+-}^2 + c_{--}^2 \end{pmatrix}. \quad (20b)$$

Note that ρ_a and ρ_b fulfill the normalization condition $\text{Tr } \rho_a = \text{Tr } \rho_b = 1$. Further, we have that $\det \rho_a = \det \rho_b = c_{+-}^2 c_{-+}^2$. Now, according to the general theory of the Schmidt decomposition [14,15], it follows that the square of the coefficients c_+ and c_- in Eq. (17) are equal to the eigenvalues λ_+ and λ_- of ρ_a (which are identical to the two eigenvalues of ρ_b). These are given by

$$c_{\pm}^2 = \lambda_{\pm} = \frac{\text{Tr } \rho_a \pm \sqrt{(\text{Tr } \rho_a)^2 - 4 \det \rho_a}}{2} = \frac{1}{2} \pm \frac{1}{2} \sqrt{1 - 4c_{+-}^2 c_{-+}^2}. \quad (21)$$

From expression (21), it follows immediately that $c_+^2 + c_-^2 = 1$. Moreover, it is important to notice that, whenever we have $c_{+-}c_{-+}c_{--} \neq 0$, then necessarily $\lambda_+ \neq \lambda_-$ (i.e., the matrices ρ_a and ρ_b are nondegenerate). This is another demonstration of the fact that, when one of the terms in expansion (2) is missing, then the resulting decomposition in Eq. (17) cannot be maximally entangled. On the other hand, the state vector $|S(\phi_a) = +1\rangle$ ($|S(\phi_a) = -1\rangle$) in Eq. (17) is just the eigenvector of ρ_a corresponding to the eigenvalue λ_+

(λ_-). Similarly, the state vector $|S(\phi_b) = +1\rangle$ ($|S(\phi_b) = -1\rangle$) is the eigenvector of ρ_b corresponding to λ_+ (λ_-).

For the particular case in which $c_{+-}^2 = c_{-+}^2 = 1/\tau^2$ and $c_{--}^2 = 1/\tau^3$ (see Eq. (12)), we have

$$c_{\pm}^2 = \frac{1}{2} \pm \frac{1}{2} \sqrt{1 - 4\tau^{-4}} = \frac{1}{2} \pm \frac{1}{2} (6\sqrt{5} - 13)^{\frac{1}{2}}. \quad (22)$$

So, the approximate values of c_+^2 and c_-^2 giving the maximum probability $P_{\eta}^{\max}$ are $c_+^2 \simeq 0.822\,648$ and $c_-^2 \simeq 0.177\,352$. Regarding the eigenvectors $|S(\phi_a) = \pm 1\rangle$ and $|S(\phi_b) = \pm 1\rangle$ that arise for this particular case, these are given by (supposing for concreteness that $\text{sgn } c_{+-} = \text{sgn } c_{-+} = \text{sgn } c_{--}$)

$$\begin{aligned} |S(\phi_a) = \pm 1\rangle &\equiv \begin{pmatrix} f_{\pm} \\ g_{\pm} \end{pmatrix}_a \\ &= \begin{pmatrix} \frac{2 - \sqrt{5} \pm (6\sqrt{5} - 13)^{\frac{1}{2}}}{\left[12\sqrt{5} - 26 \mp 2(106\sqrt{5} - 237)^{\frac{1}{2}}\right]^{\frac{1}{2}}} \\ \frac{(10\sqrt{5} - 22)^{\frac{1}{2}}}{\left[12\sqrt{5} - 26 \mp 2(106\sqrt{5} - 237)^{\frac{1}{2}}\right]^{\frac{1}{2}}} \end{pmatrix}_a, \end{aligned} \quad (23a)$$

and, (since $\rho_a = \rho_b$ for this case),³

$$|S(\phi_b) = \pm 1\rangle \equiv \begin{pmatrix} f_{\pm} \\ g_{\pm} \end{pmatrix}_b. \quad (23b)$$

Alternatively, we can also express the eigenvectors $|S(\phi_a) = \pm 1\rangle$ as

$$|S(\phi_a) = +1\rangle = \cos \frac{\delta_a}{2} |S(\theta_a) = +1\rangle - \sin \frac{\delta_a}{2} |S(\theta_a) = -1\rangle, \quad (24a)$$

$$|S(\phi_a) = -1\rangle = \sin \frac{\delta_a}{2} |S(\theta_a) = +1\rangle + \cos \frac{\delta_a}{2} |S(\theta_a) = -1\rangle, \quad (24b)$$

where $\delta_a = \theta_a - \phi_a$. Thus, for the considered case, we deduce from Eqs. (19a), (23a), and (24a) that $\delta_a = 2 \arccos f_+$. This gives us in principle the two possibilities $\delta_a \simeq \pi \pm 68.5414^\circ$, and then $\phi_a \simeq \theta_a \pm 111.4586^\circ$. Similarly, we would find that $\phi_b \simeq \theta_b \pm 111.4586^\circ$. Actually, the specific sign in front of 111.4586° to be applied for either ϕ_a or ϕ_b does generally depend on the relative signs of the coefficients c_{+-} , c_{-+} , and c_{--} in Eq. (2).

Finally we note that, as expected, the decomposition (17) fulfilling the conditions (1a)-(1d) cannot be a product state. To see this, suppose on the contrary that we have $c_+ = 0$ in Eq. (17) so that $|\eta\rangle = |S(\phi_a) = -1\rangle |S(\phi_b) = -1\rangle$. For this state, one readily finds that the fulfillment of conditions (1a)-(1d) is equivalent to requiring, respectively, that

$$\sin\left(\frac{\delta_a}{2}\right)\sin\left(\frac{\delta_b}{2}\right) = 0, \quad (25a)$$

$$\cos\left(\frac{\delta_a}{2}\right)\cos\left(\frac{\delta'_b}{2}\right) = 0, \quad (25b)$$

$$\cos\left(\frac{\delta'_a}{2}\right)\cos\left(\frac{\delta_b}{2}\right) = 0, \quad (25c)$$

$$\cos\left(\frac{\delta'_a}{2}\right)\cos\left(\frac{\delta'_b}{2}\right) \neq 0, \quad (25d)$$

where $\delta_a = \theta_a - \phi_a$, $\delta_b = \theta_b - \phi_b$, $\delta'_a = \theta'_a - \phi_a$, and $\delta'_b = \theta'_b - \phi_b$. However, as may be easily checked, the set of conditions (25a)-(25c), on the one hand, and condition (25d), on the other hand, are mutually incompatible in the sense that the fulfillment of all three conditions (25a)-(25c) precludes the fulfillment of condition (25d), and vice versa. Of course a similar remark applies to the case that $c_- = 0$.

Acknowledgment — The author wishes to thank Sibasish Ghosh and G. Kar for careful reading of an earlier draft of the manuscript and for valuable comments.

NOTES

1. The same type of contradiction is obtained if, in Eqs. (1a)-(1d), we convert all the -1 's into $+1$'s, and vice versa. Likewise, the same holds true if we reverse the sign *only* to the outcomes corresponding to particle a in each of the Eqs. (1a)-(1d). Indeed, the following set of conditions

$$\begin{aligned} P_\eta(S(\theta_a) = -1, S(\theta_b) = +1) &= 0, \\ P_\eta(S(\theta_a) = +1, S(\theta'_b) = -1) &= 0, \\ P_\eta(S(\theta'_a) = +1, S(\theta_b) = -1) &= 0, \\ P_\eta(S(\theta'_a) = +1, S(\theta'_b) = -1) &> 0, \end{aligned}$$

does also lead to a Hardy-type contradiction. Naturally, by symmetry, the same is true if we reverse the sign *only* to the outcomes corresponding to particle b in each of the Eqs. (1a)-(1d).

2. It is to be noticed that the following relations

$$\left| \left\langle S(\theta'_a) = +1 \mid S(\theta_a) = i \right\rangle \right| = 0 \iff \left| \left\langle S(\theta'_a) = -1 \mid S(\theta_a) = j \right\rangle \right| = 0,$$

and

$$\left| \left\langle S(\theta'_b) = +1 \mid S(\theta_b) = i \right\rangle \right| = 0 \iff \left| \left\langle S(\theta'_b) = -1 \mid S(\theta_b) = j \right\rangle \right| = 0,$$

hold for $i \neq j$.

3. In terms of the parameter τ , the eigenvectors $\begin{pmatrix} f_\pm \\ g_\pm \end{pmatrix}_{a,b}$ are

$$\begin{pmatrix} f_\pm \\ g_\pm \end{pmatrix}_{a,b} = \begin{pmatrix} \frac{-\tau^{-3} \pm (1-4\tau^{-4})^{\frac{1}{2}}}{[2-8\tau^{-4} \mp 2\tau^{-3}(1-4\tau^{-4})^{\frac{1}{2}}]^{\frac{1}{2}}} \\ \frac{2\tau^{-\frac{5}{2}}}{[2-8\tau^{-4} \mp 2\tau^{-3}(1-4\tau^{-4})^{\frac{1}{2}}]^{\frac{1}{2}}} \end{pmatrix}_{a,b}.$$

FIGURE CAPTIONS

FIG. 1 — Probability of jointly obtaining the results $S(\theta_a + \theta_1) = -1$ and $S(\theta_b + \theta_2) = -1$, as a function of the relative angles θ_1 and θ_2 . The surface of probability remains invariant under a reflection through the vertical planes $\theta_1 = \theta_2$, $\theta_1 + \theta_2 = 2\pi$, $\theta_1 = \pi$, and $\theta_2 = \pi$. Each of the peaks reaches a maximum value of $P_\eta^{\max} \simeq 0.090\,169$. For the peak near the origin this maximum is located at the point $\theta_1 = \theta_2 \simeq 76.3454^\circ$.

FIG. 2 — Probability of jointly obtaining the results $S(\theta_a + \theta) = -1$ and $S(\theta_b + \theta) = -1$, as a function of the single parameter θ . This curve corresponds to the interception of the surface appearing in Fig. 1 with the vertical plane $\theta_1 = \theta_2$. The maximum nonlocal effect is achieved for either $\theta \simeq 76.3454^\circ$ or $\theta \simeq 283.6546^\circ$.
